

Hematology : Lec 1.

* Body fluids :

amount depends on age, gender & amount of adipose tissue. In the average 70 kg man, the amount of body fluids = 60% of body weight (42L)

Fluids \rightarrow $\frac{2}{3}$ Intracellular, $\frac{1}{3}$ Extracellular [80% Interstitium
20% blood.

\rightarrow a comparison between the composition of IC & EC fluids.

ECF : most abundant \rightarrow cation : Na^+ , anion : Cl^-

ICF : most abundant \rightarrow cation : K^+ , anion : proteins and phosphates.

this difference is maintained thro the action of Na^+/K^+ pump (keeping Na^+ out and K^+ in).

- usually both parts of ECF (interstitial & plasma) are very similar in their components except in protein content.

Plasma has much more protein anions

the difference is due to capillaries' impermeability to proteins which contains them in the plasma.

As a result to this difference, colloid osmotic pressure is exerted by blood plasma.

\rightarrow fluid filtration and reabsorption at the level of capillaries.

At the arterial end : Blood hydrostatic pressure pushes fluids out of capillaries mainly

\rightarrow BCOP is too small to reverse the filtration, we also have IFOP favoring filtration but it's too small so it's effect isn't major.

At the venous end : BCOP pulls fluid into capillaries (reabsorption).

\rightarrow there's BHP at the venous end by it can't counteract BCOP.

this process of reabsorption & filtration, diffusion & osmosis allows for continual exchange of water and solutes between body compartments yet the volume of fluid in each compartment remains stable.

* Blood Components :

slide 7-10. (check from slides)

Plasma Proteins : imp. for creating colloid osmotic pressure and plasma's buffer capacity.

Albumin : non specific binding (bilirubin).

Fibrinogen : clotting

Globulins : α & β : specific binding (thyroid hormone, cholesterol & iron).

blood clotting & Angiotensinogen.

γ : Antibodies \rightarrow only plasma protein synthesised by WBCs not the liver like all the others.

* Hematocrit or Packed Red Cell Volume = $\frac{\text{Volume of RBCs}}{\text{Volume of blood}} \times 100\%$ \rightarrow fraction of blood composed of RBCs.

males : 40-54%

females : 38-46%

\rightarrow difference is due : 1. testosterone stimulating hematopoiesis.
2. women lose blood during menstruation.

\rightarrow Conditions that mess up the hematocrit.

higher in dehydration

lower in pregnancy due to higher plasma volumes, RBCs volume increases but less than plasma.

low hematocrit = Anemia

high hematocrit = polycythemia.

\rightarrow HCT < PCV (slightly less).

In hematocrit calculation (automated) there's no trapped plasma which can occur in spun PCVs.

* General Roles of Blood:

Transport : gases, nutrients, hormones & waste.

Regulate : pH, temperature, water content (osmotic pressure).

Protect : clotting, WBCs, antibodies

* Hemopoiesis

Early fetal life : yolk sac, later : liver, spleen, thymus & lymph nodes.

3rd trimester & : Red bone marrow

throughout life with age, red bone marrow is restricted in the axial skeleton, pectoral & pelvic girdles and proximal epiphyses of humerus & femur.

pluripotent hematopoietic stem cells

\rightarrow myeloid SC

\rightarrow different CFU

population of adult SCs found in bone marrow that are multipotent and able to self-renew.

RBCs, platelets, monocytes

neutrophils, eosinophils & basophils.

Lymphoid SC

lymphocytes and NK cells.

- similar to pluripotent SCs, but they're committed to certain cell lineage

- when cultured they give colonies of specific types of blood cells.

\rightarrow stem cells in bone marrow : reproduce themselves, proliferate & differentiate. Formed element won't divide once they leave the bone marrow except lymphocytes.

- Growth and reproduction of different types of SCs are controlled by proteins called growth inducers.

ex IL-3 : promotes growth of committed SCs.

Hemopoietic GFs for each cell type

RBCs : Erythropoietin

WBCs : Colony stimulating factors and ILs.

Platelets : Thrombopoietin.

Hematology : Lec 2

* Red Blood Cells

general features : lack nucleus, mitochondria and other organelles → can't synthesize new components.
 key enzymes: carbonic anhydrase, $\frac{1}{3}$ glycolytic enzymes → has glycogen.
 Oligosaccharides in plasma membrane → ABO and Rh blood typing.
 Production = destruction (2 million / sec).
 5.2 million / mm³ in men, 4.7 million / mm³ in women.

Features that help in gas exchange :

Hemoglobin: O₂ carrying protein.
 Biconcave: ↑ S.A, makes the cell thinner so O₂ would diffuse rapidly from innermost pt. to exterior.
 strong + flexible plasma membrane: go thro narrow capillaries without rupturing extremely pliant.
 8 um in diameter.

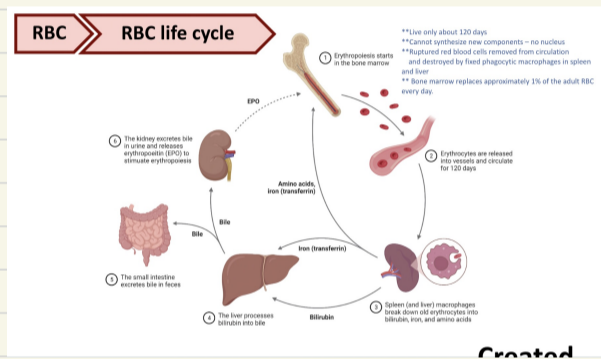

* Function + RBCs :

Oxygen and CO₂ transport thro hemoglobin.
 Contains a large amount of carbonic anhydrase which increases the rate of its rxn multiple folds [$\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+$]
 - RBCs contribute to the transport of CO₂ in 2 ways: carrying it on hemoglobin, converting it rapidly into HCO₃⁻ which allows the water + the blood to transport large amounts of CO₂ as HCO₃⁻ to the lungs to be expelled.
 Hemoglobin (as most proteins) is responsible for the buffering power of the blood.

* Hemoglobin.

- a pigment / naturally coloured: due to iron its reddish w/ O₂ and bluish when deoxygenated.
- made of 2 α-β globulin units combined with heme (porphyrin ring + iron). → most common adult form (hemoglobin A).
- Iron binds O₂ reversibly.
- transport 23% of CO₂ as it bind to A.A + hemoglobin.
- normal range 14 g/dL female, 15.5 g/dL male.

* RBCs life cycle.

RBCs rupture when they pass thro narrow spots becz the membrane becomes fragile. they can self destruct in the spleen as they pass thro its red pulp (3 um).

Break down products.

Globin's AA: reused.

iron reused

heme → bilirubin in urine

stercobilin in feces.

↳ overview: Erythropoiesis

Red bone marrow as proerythroblast, near the end the cell ejects the nucleus → reticulocyte — 1-2 days → RBC.
 During reticulocyte maturation: remaining basophilic material disappears, and it continues to make hemoglobin for the 1-2 days period.
 Total changes: Hemoglobin accumulation, nuclear condensation and reabsorption of ER.

↳ Reticulocyte count < 2% in adults.

$$= \frac{\text{no. of Reticulocytes}}{\text{no. of RBCs}} \times 100\%$$

it helps in diagnosing and typing Anemia :- Decreased : Aplastic Anemia

Increased : Hemolytic Anemia, post hemorrhage.

↳ in the state of anemia, reticulocyte % is not a true reflection of production.

we can't apply a correction factor as the percentage is already increased

→ new reticulocytes added to low Hct → increasing the percentage.

$$\text{↳ Corrected Reticulocyte count} = \text{Reticulocyte} \times \frac{\text{Act. Hct}}{\text{Nor. Hct}}$$

↳ Vitamin Requirements :-

maturation of RBCs requires vit B₁₂ + folic acid which are essential for synthesis of TTP

deficiency in either one → abnormal or diminished DNA → failure of nuclear maturation + cell division during erythropoiesis.

resulting in the production of large cells (macrocytes) w/ flimsy membranes.

↳ capable of carrying O₂ but short life span due to their fragility.

↳ Regulation of Erythropoiesis : Erythropoietin.

Low O₂ levels don't act directly on red bone marrow to increase RBCs production, instead hypoxia stimulates the kidneys to produce EPO.

EPO is a glycoprotein (90% in kidneys, 10% in liver) that stimulates production of proerythroblasts from hematopoietic SCs more rapidly.

↳ hypoxia → ↑ EPO so tissue oxygenation is an essential regulator of RBC production yet not directly.

conditions that cause hypoxia: Anemia (hemorrhage), high altitudes, prolonged cardiac failure and lung disease

↳ renal failure slows EPO release → ↓ Hct.

[Failure of O₂ absorption from blood as it passes in the lungs due to decreased blood flow.

Usually negative feedback balances production and destruction

Hematology : Lec 3

- * Hb, RBC count, Hct decline after birth due to decreased EPO + transient hemolysis.
- * Hemoglobin decrease in older adults is due to ↓ androgen in males and ↓ estrogen in females.
- * Asymptomatic elderly adults with anemia → iron deficiency and anemia + chronic disease.

* RBCs parameters

1. **MCV : mean cell volume** → avg volume (size) of RBCs

$$= \frac{\text{Hct [\%]} \times 10}{\text{RBC count million/uL}}$$
 80-100 normocytic
 > 100 macrocytic, < 80 microcytic.

bell-shaped distribution.

2. **RDW : RBC distribution width** → RBC size variation.

$$= \frac{\text{sd}}{\text{MCV}} \times 100$$
 high RDW → large variation in sizes
 low RDW → homogenous sizes.
 - high RDW associated w/ anemias + iron, B12 and folate deficiency.

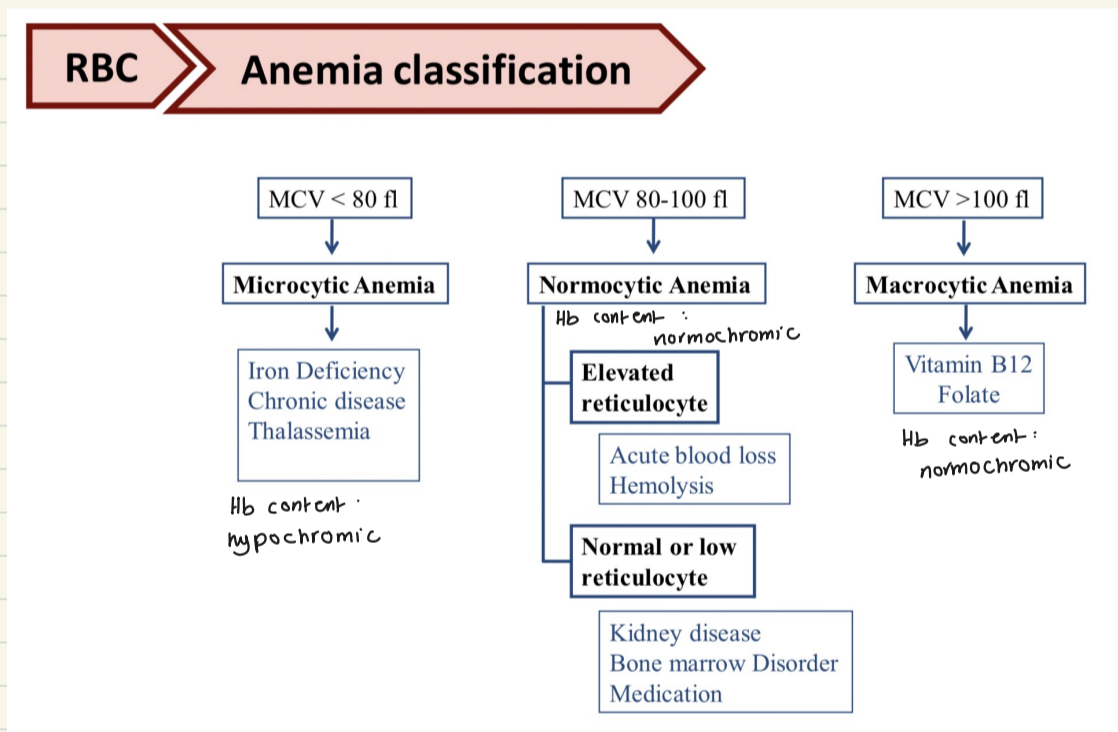

3. **MCH : mean cell Hb** → avg. Hb content in an RBC.

$$= \frac{\text{Hb} \times 10}{\text{RBC count}}$$
 normochromic 30-34
 hypochromic < 30
 - low MCH is seen as large central pale area (more than one third).

4. **MCHC : mean cell Hb concentration** → avg. Hb concentration in an RBC

$$= \frac{\text{Hb} \times 10}{\text{Hct}}$$
 it's a ratio between amount of Hb to cell volume.
 normochromic 30-36
 hypochromic < 30

- * Anemia → ↓ Production → less EPO, BM damage, Iron deficiency. low RI
- ↑ Destruction → Blood loss and hemolysis high RI

↳ effects of Anemia on CVS

- ↓ blood viscosity and resistance to blood flow on peripheral BV.
- then greater quantities of blood return to the heart
- ↳ greater cardiac output
- ↳ more pumping workload on the heart.

Hematology : Lec 4

* Thrombocytes

- formed in BM from megakaryocytes.
- $\frac{1}{2}$ -life in blood is 8-12 days with normal concentration of 150,000 - 450,000/ μ L then they get eliminated from blood by tissue macrophages in spleen.

→ cytoplasmic characteristics :-

- no nuclei
- Residues of ER and Golgi's apparatus.
- Enzyme systems for PG synthesis.
- GF for vascular endothelial cells, vascular smooth muscle cells and fibroblasts.
- contractile proteins : actin, myosin & thrombostenin.
- Mitochondria for ATP
- Fibrin stabilizing factor.

→ membrane characteristics.

- coat of glycoproteins → repels adherence to normal endothelium but causes adherence to injured areas of vessel wall.
- alot of phospholipids → activate many steps of blood-clotting process.

* Thrombocytopenia : decreased platelets.

- thousands of small hemorrhagic areas develop under the skin and throughout internal tissue, they appear red or purple.
- symptoms :- cutaneous and mucosal bleeding, easy bruising, petechiae, ↑ bleeding time.

* Hemostasis : prevention of blood loss thro :

1. vascular constriction. - if the hole is small it's closed by a platelet plug rather than clot.
2. Platelet Plug
3. blood clot as a result of coagulation.
4. Growth of fibrous tissue into the clot to close the hole permanently.

* bleeding occurs when there's a defect in B.V wall and pressure inside must be greater than outside for blood to flow out.

* small vessels are ruptured by minor traumas daily but it's handled by inherent body hemostatic mechanisms.

↳ if the vessel is larger these mechanisms are not adequate

* bleeding from severed arteries is worse than venous bleeding, as arterial blood has higher pressure so the bleeding is more profuse.

First Aid → Arterial bleeding apply pressure that is more than arterial blood pressure to minimize bleeding until it's fixed surgically.

→ Venous bleeding raise bleeding part to minimize gravity's effect. if not enough, add mild external pressure

1] vascular constriction

immediately after trauma → S.M contraction to reduce blood flow out of the vessel.

contraction results from :

local myogenic spasm, nerve reflexes, local autocooid factors from injured tissue, vascular endothelium & platelets. this spasm lasts for minutes - hours until platelet plug and coagulation take place.

2] Platelet Plug Formation

1. Adhesion : platelets don't adhere to intact endothelium, only to damaged endothelial cells and collagen on subendothelium. adherence occurs thro a plasma protein called vWF → bridge between platelets and injured vessels.

↳ vWF : secreted by megakaryocytes, platelets and endothelial cells.

2. Secretion : release of platelet granules thro formation of numerous irradiating pseudopods they secrete large amounts of ADP and thromboxane A₂ [which activates platelets and cause vaso constriction] respectively.

→ ADP + TXA₂ also activate adjacent normal endothelium to produce prostacyclin and NO these compounds inhibit platelets so that the plug is restricted to the lesion.

3. Aggregation : Platelet to Platelet cohesion

Imp. roles of platelet plug aside from physically sealing the tear :-

1. Actin-myosin complex in aggregated platelets contracts to compact & strengthen the plug.
2. Release powerful vasoconstrictors.
3. Other chemicals to enhance blood coagulation.
